

# **Dyadic Regression**

**Boston University Distinguished Visitor Lecture 1b**

*May 2022*

*Bryan S. Graham*

University of California - Berkeley

Dyadic regression analyses are abundant in social science research (see below).

In economics they date (at least) to Tinbergen's (1962) pioneering analysis of trade flows.

While frequently used by empirical researchers, dyadic regression analysis lacks inferential foundations.

Widely varying approaches to hypothesis testing used in practice.

# Tinbergen (1962, SWE, Table VI-1)

FACTORS DETERMINING THE SIZE OF INTERNATIONAL TRADE FLOWS  
Results of Calculations A (18 countries)

$$\log E_{ij} = \alpha_1 \log Y_i + \alpha_2 \log Y_j + \alpha_3 \log D_{ij} + \alpha_4 \log N + \alpha_5 \log P_C + \alpha_6 \log P_B + \alpha'_0$$

Calculation No.	ESTIMATED VALUE OF THE COEFFICIENTS							Correlation Coefficient
	$\alpha_1$	$\alpha_2$	$\alpha_3$	$\alpha_4$	$\alpha_5$	$\alpha_6$	$\alpha'_0$

*Notes:* The dependent variable = 1 if *i* cites *j* as the source of mutual insurance, 0 otherwise. Estimator is logit. All *t*-values based on standard errors corrected for dyadic correlation of errors.

<sup>a</sup> Instrumented variables—see text for details.

<sup>b</sup> Small cluster of 15–20 households.

## How to Conduct Inference?

Dyads present an ironic situation in that dyadic data sets, with 100,000 cases (or often considerably more), may seem ideal for hypothesis testing. Yet, the structure of dyadic data complicates the assessment to statistical significance. **Because dyadic observations are not independent events, the usual tests of significance result in overconfidence**, even when the model itself appears to be correctly specified (Erikson, Pinto & Rader, 2014, p. 457).

## How to Conduct Inference? (continued)

Dyadic observations are not independent. This is due to the presence of individual-specific factors common to all observations involving that individual. It is thus reasonable to assume that  $\mathbb{E}[u_{ij}u_{ik}] \neq 0$  for all  $k$  and  $\mathbb{E}[u_{ij}u_{kj}] \neq 0$  for all  $k$ . By the same reasoning, we also have  $\mathbb{E}[u_{ij}u_{jk}] \neq 0$  and  $\mathbb{E}[u_{ij}u_{ki}] \neq 0$ . Provided that regressors are exogenous,...OLS...yields consistent coefficient estimates but standard errors are inconsistent, leading to incorrect inference (Fafchamps and Gubert, 2007, p. 330).

## Existing suggestions

1. Permutation approaches: quadratic assignment procedure (QAP) of Hubert (1985, PM), Krackhardt (1988, SN)
2. Integrated likelihood/MCMC:  $p_2$  model of van Duijn, Snijders and Zijlstra (2004, SN), Zijlstra, van Duijn and Snijders (2009, BJMSP), Krivitsky, Handcock, Raftery and Hoff (2009, SN) – emerging frequentist theory.

### Existing suggestions (continued)

3. Pairwise/composite likelihood: Bellio and Varin (2005, SM).
4. Dyadic cluster-robust s.e.: Fafchamps and Gubert (2007, JDE), Cameron and Miller (2014, WP), Aronow, Samii and Assenova (2015, PA), Tabord-Meehan (2018, JBES).
  - Frequentist theory for these approaches is very new (e.g., Graham, 2020a,b; Menzel, 2021).

## Dyadic Regression: Notation & Setup

Let  $i \in \mathbb{N}$  index agents in an infinite population of interest. Observable attribute  $X_i \in \mathbb{X} = \{x_1, \dots, x_L\}$ .

Attribute partitions the population into  $L = |\mathbb{X}|$  subpopulations which I will refer to as “types”.

Let  $\mathbb{N}(x) = \{i : X_i = x_l\}$  is the index set for type  $l$  agents.

## Dyadic Regression: Notation & Setup

Associated with each ordered pair of agents is the scalar directed outcome  $Y_{ij} \in \mathbb{Y} \subseteq \mathbb{R}$ .

I will refer to agent  $i$  as the “ego” of the directed dyad and agent  $j$  as its “alter”.

In the context of the trade example the ego agent is the exporting country, the alter the importing one.

The *adjacency matrix*  $[Y_{ij}]_{i,j \in \mathbb{N}}$  collects all such outcomes into an infinite random array.

## Within-type or X-Exchangeability

From the standpoint of the econometrician, the indexing of agents within subpopulations homogenous in  $X_i$  is arbitrary: agents of the same type are exchangeable.

Exchangeability of agents within subpopulations homogenous in  $X_i$  induces a particular form of exchangeability on the adjacency matrix.

This form of exchangeability, in turn, induces a particular form of dependence across the rows and columns of  $[Y_{ij}]_{i,j \in \mathbb{N}}$ .

The structure of this dependence allows for the formulation of LLNs and CLTs.

## Within-type or X-Exchangeability (continued)

Let  $\sigma_x : \mathbb{N} \rightarrow \mathbb{N}$  be any permutation of a finite number of the agent indices which satisfies the restriction

$$\left[ X_{\sigma_x(i)} \right]_{i \in \mathbb{N}} = [X_i]_{i \in \mathbb{N}}. \quad (1)$$

Condition (1) constrains index permutations to occur among agents of the same type.

A network is *relatively exchangeable* with respect to  $X$  (or  $X$ -exchangeable) if

$$\left[ Y_{\sigma_x(i)\sigma_x(j)} \right]_{i,j \in \mathbb{N}} \stackrel{D}{=} [Y_{ij}]_{i,j \in \mathbb{N}} \quad (2)$$

for all permutations  $\sigma_x$  satisfying (1).

$X$ -exchangeability is a natural generalization of joint exchangeability, as introduced in the context of Aldous-Hoover Theorem.

## Graphon & Dyadic Regression Function

Let  $\alpha$ ,  $\{(U_i, X_i)\}_{i \geq 1}$  and  $\{(V_{ij}, V_{ji})\}_{i \geq 1, j \geq 1}$  be (sequences of ) i.i.d. random variables, additionally independent of one another.

Consider the random array  $[Y_{ij}^*]_{i,j \in \mathbb{N}}$  generated according to the rule

$$Y_{ij}^* = \tilde{h}(\alpha, X_i, X_j, U_i, U_j, V_{ij}) \quad (3)$$

with  $\tilde{h} : [0, 1] \times \mathbb{X} \times \mathbb{X} \times [0, 1]^3 \rightarrow \mathbb{Y}$  a measurable function.

A graph generated according to (3) is  $X$ -exchangeable.

## Graphon & Dyadic Regression Function (continued)

Here  $\alpha$  is a mixing parameter analogous to the one appearing in de Finetti's (1931) original representation theorem.

I will depress the dependence of  $\tilde{h}$  on  $\alpha$ , defining the notation  $h(X_i, X_j, U_i, U_j, V_{ij}) \stackrel{def}{=} \tilde{h}(\alpha, X_i, X_j, U_i, U_j, V_{ij})$ .

The function  $h : \mathbb{X} \times \mathbb{X} \times [0, 1]^3 \rightarrow \mathbb{Y}$  will be referred to as a **graphon**.

## Graphon & Dyadic Regression Function (continued)

Crane and Towsner (2018), in an extension of the Aldous-Hoover representation result, show that for any  $X$ -exchangeable random array  $[Y_{ij}]_{i,j \in \mathbb{N}}$  there exists another array  $[Y_{ij}^*]_{i,j \in \mathbb{N}}$  generated according to (3) such that the two arrays have the same distribution:

$$[Y_{ij}]_{i,j \in \mathbb{N}} \stackrel{D}{=} [Y_{ij}^*]_{i,j \in \mathbb{N}}. \quad (4)$$

We can therefore use (3) as an ‘as if’ non-parametric data generating process for  $[Y_{ij}]_{i,j \in \mathbb{N}}$ ; this will facilitate a variety of probabilistic calculations (e.g., computing conditional expectations, variances and, especially, covariances).

## Sampling

Let  $i = 1, \dots, N$  index a simple random sample from the target population.

For each of the  $N$  sampled units the econometrician observes  $X_i$  and for each of the  $\binom{N}{2}$  sampled dyads she observes  $(Y_{ij}, Y_{ji})$ .

## Composite Likelihood

Let  $\{f_{Y_{12}|X_1, X_2}(Y_{12}|X_1, X_2; \theta) : \theta \in \Theta \subseteq \mathbb{R}^{\dim(\theta)}\}$  be a parametric family of distributions for the conditional distribution of  $Y_{12}$  given  $X_1$  and  $X_2$ .

We might model trade from exporter  $i$  to importer  $j$  given covariates as a Poisson random variable:

$$f_{Y_{12}|X_1, X_2}(y_{ij}|X_i, X_j; \theta) = \exp[-\exp[W'_{ij}\theta]] \frac{\{\exp[W'_{ij}\theta]\}^{y_{ij}}}{y_{ij}!} \quad (5)$$

with  $y_{ij} = 0, 1, 2, \dots$  and  $W_{ij} \stackrel{def}{=} w(X_i, X_j)$  a known  $J \times 1$  vector of functions of  $X_i$  and  $X_j$ .

## Composite Likelihood (continued)

If  $X_i = (\ln \text{GDP}_i, \text{LAT}_i, \text{LONG}_i)'$ , then setting

$$W_{ij} = \begin{pmatrix} \ln \text{GDP}_i & \ln \text{GDP}_j \\ \ln \left[ (\text{LAT}_i - \text{LAT}_j)^2 + (\text{LONG}_i - \text{LONG}_j)^2 \right]^{1/2} \end{pmatrix}$$

results in a basic gravity trade model specification.

## Composite Likelihood (continued)

(5) only specifies the marginal distribution of  $Y_{ij}$  given  $X_i$  and  $X_j$ .

The econometrician is not asserting, for example, that

$$f_{Y_{12}, Y_{13} | X_1, X_2, X_3}(y_{12}, y_{13} | X_1, X_2, X_3; \theta) = f_{Y_{12} | X_1, X_2}(y_{12} | X_1, X_2; \theta) \\ \times f_{Y_{13} | X_1, X_2}(y_{13} | X_1, X_3; \theta);$$

since doing so would imply independence of  $Y_{12}$  and  $Y_{13}$  given covariates.

## Composite Likelihood (continued)

Formulating a conditional likelihood for the entire adjacency matrix  $\mathbf{Y} \stackrel{\text{def}}{=} [Y_{ij}]_{1 \leq i, j \leq N, i \neq j}$  given  $\mathbf{X} \stackrel{\text{def}}{=} [X_i]_{1 \leq i \leq N}$  would require an explicit specification of the dependence structure across dyads sharing agents in common.

In contrast  $f_{Y_{12}|X_1, X_2}(Y_{12}|X_1, X_2; \theta)$ , which is a model for the marginal distribution of  $Y_{12}$  alone, does not require modeling this dependence.

## Composite Likelihood (continued)

Let  $l_{ij}(\theta) = \ln f_{Y_{12}|X_1, X_2}(Y_{ij}|X_i, X_j; \theta)$  and consider the estimator which chooses  $\hat{\theta}$  to maximize:

$$\hat{\theta} = \arg \max_{\theta \in \Theta} \frac{1}{N(N-1)} \sum_{i=1}^N \sum_{j \neq i} l_{ij}(\theta). \quad (6)$$

Because its summands are not independent of one another – at least those sharing indices in common are not – (6) does not correspond to a log-likelihood function for  $\mathbf{Y}$  given  $\mathbf{X}$ .

Instead it corresponds to what is sometimes called a composite log-likelihood.

## **Composite Likelihood (continued)**

While an appropriately specified composite log-likelihood typically delivers a valid estimating equation, accurate inference is more challenging

The unmodeled dependence structure in the data needs to be explicitly taken into account at the inference stage.

## Limit Distribution

A mean value expansion of the first order condition associated with the maximizer of (6) yields,

$$\sqrt{N}(\hat{\theta} - \theta_0) = [-H_N(\bar{\theta})]^+ \sqrt{N}S_N(\theta_0)$$

with  $\bar{\theta}$  a mean value between  $\hat{\theta}$  and  $\theta_0$  which may vary from row to row and the  $+$  superscript denoting a Moore-Penrose inverse.

Here  $S_N(\theta_0)$  is the “score” vector

$$S_N(\theta) = \frac{1}{N} \frac{1}{N-1} \sum_i \sum_{j \neq i} s_{ij}(Z_{ij}, \theta) \quad (7)$$

with  $s(Z_{ij}, \theta) = \partial l_{ij}(\theta) / \partial \theta$  for  $Z_{ij} = (Y_{ij}, X'_i, X'_j)'$  and  $H_N(\theta) = \frac{1}{N} \frac{1}{N-1} \sum_i \sum_{j \neq i} \frac{\partial^2 l_{ij}(\theta)}{\partial \theta \partial \theta'}$ .

## Limit Distribution (continued)

If the Hessian matrix  $H_N(\bar{\theta})$  converges in probability to the invertible matrix  $\Gamma_0$ , as I will assume, then

$$\sqrt{N}(\hat{\theta} - \theta_0) = -\Gamma_0^{-1}\sqrt{N}S_N(\theta_0) + o_p(1)$$

so that the asymptotic sampling properties of  $\sqrt{N}(\hat{\theta} - \theta_0)$  will be driven by the behavior of  $\sqrt{N}S_N(\theta_0)$ .

As with the composite log-likelihood criterion function, the summands of  $\sqrt{N}S_N(\theta_0)$  are not independent of one another.

A standard central limit theorem cannot be used to demonstrate asymptotic normality of  $\sqrt{N}S_N(\theta_0)$ .

## Limit Distribution (continued)

Fortunately  $S_N(\theta_0)$ , although not a U-Statistic, has a dependence structure similar to one. This insight can be used to derive the limit properties of  $\sqrt{N}(\hat{\theta} - \theta_0)$ .

Begin by re-writing  $S_N(\theta_0)$  as

$$S_N = \binom{N}{2}^{-1} \sum_{i=1}^{N-1} \sum_{j=i+1}^N \frac{s_{ij} + s_{ji}}{2}, \quad (8)$$

where  $s_{ij} \stackrel{\text{def}}{=} s(Z_{ij}, \theta_0)$  and  $S_N \stackrel{\text{def}}{=} S_N(\theta_0)$ .

While (8) has the cursory appearance of a U-Statistic it is, in fact not one:  $Y_{ij}$ , which enters  $s_{ij}$ , varies at the dyad level, hence  $S_N$  is not a function of  $N$  i.i.d. random variables.

## Limit Distribution (continued)

Let  $\mathbf{U} = [U_i]_{1 \leq i \leq N}$ ; the projection of  $S_N$  onto the *observed* covariate matrix  $\mathbf{X}$  and the *unobserved* vector of unit-specific effects  $\mathbf{U}$  equals:

$$V_N \stackrel{def}{=} \mathbb{E}[S_N | \mathbf{X}, \mathbf{U}] = \binom{N}{2}^{-1} \sum_{i < j} \frac{\bar{s}_{ij} + \bar{s}_{ji}}{2} \quad (9)$$

with  $\bar{s}_{ij} \stackrel{def}{=} \bar{s}(X_i, U_i, X_j, U_j)$  and

$$\bar{s}(X_i, U_i, X_j, U_j) \stackrel{def}{=} \mathbb{E} \left[ s(Z_{ij}, \theta_0) \middle| X_i, U_i, X_j, U_j \right].$$

## Limit Distribution (continued)

The projection (9) is a U-statistic of order two: specifically it is a summation over all  $\binom{N}{2}$  dyads that can be formed from the i.i.d. sample  $\{(X_i, U_i)\}_{1 \leq i \leq N}$ .

Unusually our U-statistic is defined in terms of a combination of both *observed*  $\{X_i\}_{1 \leq i \leq N}$  and *unobserved*  $\{U_i\}_{1 \leq i \leq N}$  random variables.

The projection error  $T_N = S_N - V_N$  consists of a summation of  $\binom{N}{2}$  conditionally uncorrelated summands; hence  $\mathbb{V}(T_N) = \binom{N}{2}^{-1} \mathbb{E} \left( \mathbb{V} \left( \frac{s_{12} + s_{21}}{2} \middle| X_1, U_1, X_2, U_2 \right) \right) = O(N^{-2})$ .

We also have that  $T_N$  and  $V_N$  are uncorrelated by construction.

## Limit Distribution (continued)

Although we cannot numerically compute  $V_N$  – even if  $\theta_0$  is known – because the  $\{U_i\}_{1 \leq i \leq N}$  are unobserved, we can use the theory of U-statistics to characterize its sampling properties as  $N \rightarrow \infty$ .

Decomposing  $V_N$  into a Hájek projection and a second remainder term yields:

$$V_N = V_{1N} + V_{2N}.$$

## Limit Distribution (continued)

Continuing from the prior slide...

$$V_{1N} = \frac{2}{N} \sum_{i=1}^N \left\{ \frac{\bar{s}_1^e(X_i, U_i) + \bar{s}_1^a(X_i, U_i)}{2} \right\} \quad (10)$$

$$V_{2N} = \binom{N}{2}^{-1} \sum_{i < j} \left\{ \frac{\bar{s}_{ij} + \bar{s}_{ji}}{2} - \frac{\bar{s}_1^e(X_i, U_i) + \bar{s}_1^a(X_i, U_i)}{2} - \frac{\bar{s}_1^e(X_j, U_j) + \bar{s}_1^a(X_j, U_j)}{2} \right\}. \quad (11)$$

where  $\bar{s}^e(x, u) = \mathbb{E}[\bar{s}(x, u, X_1, U_1)]$  and  $\bar{s}^a(x, u) = \mathbb{E}[\bar{s}(X_1, U_1, x, u)]$ .

The superscript ‘e’ denotes ‘ego’, while ‘a’ denotes ‘alter’.

### Limit Distribution (continued)

Conveniently  $V_{1N}$  is a sum of i.i.d. random variables to which, after scaling by  $\sqrt{N}$ , a CLT may be applied.

Furthermore it can be shown that  $\mathbb{V}(V_{2N}) = O(N^{-2})$ .

## Limit Distribution (continued)

Putting these results together yields the asymptotically linear representation

$$\begin{aligned}\sqrt{N}(\hat{\theta} - \theta_0) &= -\Gamma_0^{-1}\sqrt{N}(V_{1N} + V_{2N} + T_N) + o_p(1) \\ &= -\Gamma_0^{-1}\sqrt{N}V_{1N} + o_p(1) \\ &= -\Gamma_0^{-1}\frac{2}{\sqrt{N}}\sum_{i=1}^N\left\{\frac{\bar{s}_1^e(X_i, U_i) + \bar{s}_1^a(X_i, U_i)}{2}\right\} + o_p(1),\end{aligned}$$

and hence a limit distribution for  $\sqrt{N}(\hat{\theta} - \theta_0)$  of

$$\sqrt{N}(\hat{\theta} - \theta_0) \xrightarrow{D} \mathcal{N}\left(0, 4(\Gamma_0' \Sigma_1^{-1} \Gamma_0)^{-1}\right) \quad (12)$$

where  $\Sigma_1 = \mathbb{V}\left(\frac{\bar{s}_1^e(X_1, U_1) + \bar{s}_1^a(X_1, U_1)}{2}\right)$ .

## Bootstrap

Rewriting our dyadic regression coefficient estimate in pseudo-U-Process form yields

$$\hat{\theta} = \arg \max_{\theta \in \Theta} \frac{2}{N(N-1)} \sum_{i=1}^{N-1} \sum_{j=i+1}^N \left\{ \frac{l_{ij}(\theta) + l_{ji}(\theta)}{2} \right\}.$$

Next let  $\{V_i^b\}_{i=1}^N$  be a sequence of i.i.d. mean one random weights independent of the data.

One such sequence is drawn for each of  $b = 1, \dots, B$  bootstrap replications.

## Bootstrap (continued)

In the  $b^{th}$  such replication we compute

$$\hat{\theta}_b = \arg \max_{\theta \in \Theta} \frac{2}{N(N-1)} \sum_{i=1}^{N-1} \sum_{j=i+1}^N V_i^b V_j^b \left\{ \frac{l_{ij}(\theta) + l_{ji}(\theta)}{2} \right\}.$$

The bootstrap distribution  $\{\hat{\theta}_b\}_{b=1}^B$  can then be used to approximate the sampling distribution of  $\hat{\theta}$ .

Letting  $V_i^b$  be an exponential random variable with rate parameter 1 results in a (pseudo-) Bayesian bootstrap (Janssen, 1994).

If we let  $V_i^b$  equal the number of times agent  $i$  is sampled from the set  $\{1, \dots, N\}$  across  $N$  draws with replacement we get the proposal of Davezies et al (2019).
